(Dated: March 26, 2014)

Electron lenses are pulsed, magnetically confined electron beams whose current-density profile is shaped to obtain the desired effect on the circulating beam in high-energy accelerators. They were used in the Fermilab Tevatron collider for abort-gap clearing, beam-beam compensation, and halo scraping. A beam-beam compensation scheme based upon electron lenses is currently being implemented in the Relativistic Heavy Ion Collider at Brookhaven National Laboratory. This work is in support of a conceptual design of hollow electron beam scraper for the Large Hadron Collider. It also applies to the implementation of nonlinear integrable optics with electron lenses in the Integrable Optics Test Accelerator at Fermilab. We consider the axial asymmetries of the electron beam caused by the bends that are used to inject electrons into the interaction region and to extract them. A distribution of electron macroparticles is deposited on a discrete grid enclosed in a conducting pipe. The electrostatic potential and electric fields are calculated using numerical Poisson solvers. The kicks experienced by the circulating beam are estimated by integrating the electric fields over straight trajectories. These kicks are also provided in the form of interpolated analytical symplectic maps for numerical tracking simulations, which are needed to estimate the effects of the electron lens imperfections on proton lifetimes, emittance growth, and dynamic aperture. We outline a general procedure to calculate the magnitude of the transverse proton kicks, which can then be generalized, if needed, to include further refinements such as the space-charge evolution of the electron beam, magnetic fields generated by the electron current, and longitudinal proton dynamics.

## I. INTRODUCTION

Electron lenses are pulsed, magnetically confined electron beams whose current-density profile is shaped to obtain the desired effect on the circulating beam in high-energy accelerators. Electron lenses were used in the Fermilab Tevatron collider for bunch-by-bunch compensation of long-range beam-beam tune shifts, for removal of uncaptured particles in the abort gap, for preliminary experiments on head-on beam-beam compensation, and for the demonstration of halo scraping with hollow electron beams. Electron lenses for beam-beam compensation were built for the Relativistic Heavy Ion Collider at Brookhaven National Laboratory and are currently being commissioned. Electron lenses represent one of the most promising options to cope with the challenges of beam halo scraping and control in the Large Hadron Collider [1, 2]. They are also one of the candidate lattice elements to achieve nonlinear integrable optics in the Integrable Optics Test Accelerator at Fermilab [3, 4].

Applications of electron lenses often rely on the axial symmetry of the electrons' current distribution. For instance, in a hollow electron beam scraper, the halo of the circulating beam is affected by the electromagnetic fields generated by the electrons [5]. The beam core is unaffected only if the distribution of the electron charge is axially symmetric. One cause of asymmetry is the space-charge evolution of the electron beam as it propagates through the electron lens. In this note, we consider another effect: the bends that are usually used to inject and extract the electron beam from the interaction region (Figure 1). Although small, these asymmetries may have detectable effects on core lifetimes and emittances because of their nonlinear nature, especially when the current of the electron pulse is changed turn by turn to enhance the halo removal effect by resonant excitation of selected particles.

## II. GENERATION OF THE ELECTRON MACROPARTICLES

In this note, we focus on the configuration of hollow electron lenses for the LHC. The parameters of the proton beam are used to calculate beam sizes in the interaction region. Typical values are reported in Table I. We assume a round proton beam with an rms beam size  $\sigma_p = 0.317$  mm.

The hollow electron beam is represented by a cylindrical bent pipe with a curvature radius  $R = 0.7$  m, inner radius  $r_i = 1.268$  mm  $= 4\sigma_p$ , and outer radius  $r_o = 2.386$  mm. The ratio between the outer and the inner radius is chosen to reproduce the dimensions of the cathode in the existing 1-inch hollow electron gun that was built as LHC prototype [6, 7]:  $(12.7 \text{ mm})/(6.75 \text{ mm})$ . The bent tube of electrons spans a bend angle of  $\theta = 30$  deg. A total of  $N_e = 1048576$  electron macroparticles is used to reproduce the static charge density distribution of a 1-A, 5-keV electron beam.

A subsample of the distribution of macroparticles is shown in Figure 2. The  $z$ -axis is chosen along the direction of the circulating proton beam. The  $x$ -axis points horizontally outward. The upward direction is represented by the  $y$ -axis. The origin of the coordinate system coincides with the point where the axis of the bent electron beam intersects the axis of the circulating beam.

### III. CALCULATION OF ELECTROSTATIC FIELDS

A multigrid Poisson solver within the Warp particle-in-cell code [8] is used to calculate the electrostatic fields. The Dirichlet boundary conditions are defined by a long cylindrical main beam pipe and by a cylindrical injection beam pipe stub, joining the main pipe at an angle (Figure 3). This arrangement is a simplified version of the injection scheme in the Tevatron electron lenses (Figure 1). Both pipes have an inner radius  $r_{\text{pipe}} = 40$  mm. The injection pipe is centered on the midpoint  $(x_C, y_C = 0, z_C)$  along the electron beam arc between the starting edge of the electron beam and the intersection point between the curved electron beam axis and the main pipe. The axis of the injection pipe is tangent to the electron beam axis at  $(x_C, y_C = 0, z_C)$ .

Space is subdivided into 2 discrete grids, a coarse one and a fine one. The coarse mesh has a spacing of 2 mm and covers the whole simulated space, which extends at least 1 beam pipe radius beyond the charge distribution of the system. The fine mesh is constructed around the hypothetical central trajectory of the circulating proton beam. Its spacing is 0.099 mm, or a fraction of  $\sigma_p$ . It extends longitudinally for the whole length of the simulated space. The coverage of the fine mesh is designed to obtain kick maps for both the core and the halo of the proton beam. We therefore define a region of interest:  $|x| \leq 10\sigma_p$  and  $|y| \leq 10\sigma_p$ , with  $10\sigma_p = 3.17$  mm. The fine mesh extends beyond the region of interest to smoothly connect with the coarse mesh.

Numerical simulations are run on Linux machines. A full calculation takes a few minutes on a single processor core. For the coarse mesh, all the relevant data is written to file: mesh coordinates, charge density, electrostatic potential, electric field components. For the fine mesh, only the integrated fields are saved (as described below). Data analysis, scripting, and report generation are done with the multi-platform, open-source statistical software R [9].

Figure 3 shows the electrostatic potential on the  $xz$ -plane of the bend. A section of the conductors is marked by the 0-V equipotential lines and by the grid points in light gray. The potential near the center of the electron beam is  $-1.2$  kV.

The electrostatic potential and the components of the electric field on the  $z$ -axis (axis of the proton beam) of the coarse mesh are shown in Figure 4. As most of the charge lies on the  $x < 0$  side of the  $zy$ -plane, the  $x$ -

component of the electric field is negative. Because of symmetry, the vertical component  $E_y$  should vanish. Its small fluctuations show the effect of the discrete distribution of charge. As expected, the  $z$ -component of the electric field is positive for large negative  $z$ , whereas it becomes negative after the protons cross the negative charge distribution.

#### IV. CALCULATION OF THE TRANSVERSE PROTON KICKS

The electrostatic fields are integrated over straight paths to estimate the kicks on the circulating proton beam. Only transverse kicks are considered, as the longitudinal kicks of two symmetric bends cancel out for high-energy protons. The transverse kicks due to two bends, on the other hand, have the same sign and will add up. The typical angles of the proton trajectories are of the order of  $\sqrt{\gamma\epsilon} \simeq \sqrt{\epsilon/\beta} = 1.6 \mu\text{rad}$  (Table I), where  $\gamma \equiv (1 + \alpha^2)/\beta$  and  $\alpha \equiv (-1/2)(d\beta/dz)$  are Courant-Snyder lattice parameters. The resulting position variations of the protons over the length of the bend are therefore neglected.

The integrated electrical potential over the proton trajectory,

$$V(x, y) = \int_{z_1}^{z_2} \phi(x, y, z) dz, \quad (1)$$

is shown in Figure 5.

From Newton's second law, and neglecting magnetic effects, the transverse kick  $\Delta p$  is related to the impulse of the electrostatic force  $F$ :

$$\Delta p_{x,y} = \int_{t_1}^{t_2} F_{x,y} dt = \frac{q}{v_z} \int_{z_1}^{z_2} E_{x,y} dz \quad (2)$$

$$\Delta x', \Delta y' = \frac{\Delta p_{x,y}}{p_z} = \frac{q}{\beta_p^2 \gamma_p m_p c^2} \int_{z_1}^{z_2} E_{x,y} dz = \frac{1}{(B\rho)_p \cdot v_z} \int_{z_1}^{z_2} E_{x,y} dz, \quad (3)$$

where  $q$ ,  $v$ ,  $\beta_p$ ,  $\gamma_p$ ,  $m_p c^2$ ,  $(B\rho)_p$  are the charge, velocity, relativistic factors, rest energy, and magnetic rigidity of the circulating beam, and  $t$  is time. The integrated electric fields (loosely referred to as 'kicks') are defined as follows:

$$k_x(x, y) \equiv \int_{z_1}^{z_2} E_x(x, y, z) dz, \quad (4)$$

$$k_y(x, y) \equiv \int_{z_1}^{z_2} E_y(x, y, z) dz, \quad (5)$$

and can be applied to particles of different magnetic rigidities. The results of the calculation are shown in Figure 6. Protons on axis experience a negative horizontal integrated field of  $-9.1 \text{ kV}$ , whereas the vertical kick vanishes. For 7-TeV protons, for instance, an integrated field of  $10 \text{ kV}$  generates an angular deviation of  $1.4 \text{ nrad}$ .

For tracking simulations, one could interpolate the kick maps of Figure 6 in 2 dimensions for each particle. Alternatively, for better accuracy and to speed up calculations, we look for an analytical symplectic parameterization of the functions  $k_x(x, y)$  and  $k_y(x, y)$ .

## V. PARAMETERIZATION OF THE TRANSVERSE KICKS

The integrated potential is parameterized in terms of the tensor product of Chebyshev polynomials of the first kind up to order  $N$  [10]:

$$\begin{aligned} V(x, y) &= C_{00} + C_{10} \cdot T_1\left(\frac{x}{a}\right) + C_{01} \cdot T_1\left(\frac{y}{a}\right) + \\ &\quad C_{20} \cdot T_2\left(\frac{x}{a}\right) + C_{11} \cdot T_1\left(\frac{x}{a}\right) \cdot T_1\left(\frac{y}{a}\right) + C_{02} \cdot T_2\left(\frac{y}{a}\right) + \dots \\ &= \sum_{n=0}^N \sum_{j=0}^n C_{j, (n-j)} \cdot T_j\left(\frac{x}{a}\right) \cdot T_{n-j}\left(\frac{y}{a}\right) \end{aligned} \quad (6)$$

where  $C_{jl}$  are  $(N+1)(N+2)/2$  dimensional coefficients (in units of  $V \cdot m$ , for instance) and  $T_n(u)$  are Chebyshev polynomials of order  $n$  in the variable  $u$ :

$$\begin{aligned} T_0(u) &= 1 \\ T_1(u) &= u \\ T_n(u) &= 2u \cdot T_{n-1}(u) - T_{n-2}(u). \end{aligned} \quad (7)$$

This parameterization is chosen because, in the interval  $u \in [-1, 1]$ , Chebyshev polynomials are orthogonal, making the coefficients independent of each other, and bounded,  $T_n(u) \in [-1, 1]$ , making the coefficients of the same order of magnitude. (Because of the nonzero electron charge density on the proton trajectory, the electric potential does not satisfy Laplace's equation and it cannot be derived from a complex harmonic potential decomposable as a superposition of multipoles.) The coordinates  $x$  and  $y$  are expressed in units of an arbitrary length scale ( $a = 3.2$  mm for our region of interest), to ensure that the argument of the polynomials is contained within the unit interval. Because of the symmetry of the charge distribution, the potential should be an even function of  $y$  and only contain even powers of the vertical coordinate. We therefore require

$$C_{j1} = C_{j3} = C_{j5} = \dots = 0 \quad (8)$$

for any order  $j$  of the polynomials in  $x$ .

The kicks are obtained by derivation of the integrated potential:

$$\begin{aligned} k_x(x, y) &= -\frac{\partial V}{\partial x} = -\frac{1}{a} \sum_{n=0}^N \sum_{j=0}^n C_{j, (n-j)} \cdot T'_j\left(\frac{x}{a}\right) \cdot T_{n-j}\left(\frac{y}{a}\right) \\ k_y(x, y) &= -\frac{\partial V}{\partial y} = -\frac{1}{a} \sum_{n=0}^N \sum_{j=0}^n C_{j, (n-j)} \cdot T_j\left(\frac{x}{a}\right) \cdot T'_{n-j}\left(\frac{y}{a}\right). \end{aligned} \quad (9)$$

The derivatives of the Chebyshev polynomials  $T'_n(u)$  can be calculated recursively as follows:

$$(1 - u^2) \cdot T'_n(u) = n \cdot [T_{n-1}(u) - u \cdot T_n(u)], \quad (10)$$

or from their trigonometric representation:

$$T'_n(u) = \frac{n \cdot \sin[n \cdot \arccos(u)]}{\sqrt{1 - u^2}}. \quad (11)$$

The cross derivatives of the kicks are

$$\frac{\partial k_x}{\partial y} = \frac{\partial k_y}{\partial x} = -\frac{1}{a^2} \sum_{n=0}^N \sum_{j=0}^n C_{j, (n-j)} \cdot T'_j\left(\frac{x}{a}\right) \cdot T'_{n-j}\left(\frac{y}{a}\right). \quad (12)$$

This ensures that the  $z$  component of the curl of the integrated electric field is zero. This is a necessary and sufficient condition for the  $4 \times 4$  Jacobian matrix  $\mathbf{J}$  of initial and final transverse coordinates  $(x^i, y^i; x^f, y^f)$  and momenta  $(p_x^i, p_y^i; p_x^f, p_y^f)$

$$\mathbf{J} \equiv \begin{pmatrix} \partial x^f / \partial x^i & \partial x^f / \partial p_x^i & \partial x^f / \partial y^i & \partial x^f / \partial p_y^i \\ \partial p_x^f / \partial x^i & \partial p_x^f / \partial p_x^i & \partial p_x^f / \partial y^i & \partial p_x^f / \partial p_y^i \\ \partial y^f / \partial x^i & \partial y^f / \partial p_x^i & \partial y^f / \partial y^i & \partial y^f / \partial p_y^i \\ \partial p_y^f / \partial x^i & \partial p_y^f / \partial p_x^i & \partial p_y^f / \partial y^i & \partial p_y^f / \partial p_y^i \end{pmatrix} \equiv \begin{pmatrix} 1 & 0 & 0 & 0 \\ q & 1 & r & 0 \\ 0 & 0 & 1 & 0 \\ s & 0 & t & 1 \end{pmatrix} \quad (13)$$

to be symplectic:

$$\mathbf{J}^T \mathbf{S} \mathbf{J} - \mathbf{S} = \begin{pmatrix} 0 & 0 & (s-r) & 0 \\ 0 & 0 & 0 & 0 \\ (r-s) & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \text{ with } \mathbf{S} \equiv \begin{pmatrix} 0 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \end{pmatrix}, \quad (14)$$

because  $s = r$  at any order of approximation.

In the region of interest, we have  $M = 4032$  calculated points, each represented by the coordinates  $[x_i, y_i]$  and fields  $[V_i, (k_x)_i, (k_y)_i]$ , with  $i = 1, \dots, M$ . The polynomial model is applied simultaneously (i.e., with the same coefficients) to the integrated potential and to the kicks. Fitting only the integrated potential would

introduce spurious effects in its derivatives as the order increases, whereas a fit to only the kicks cannot determine  $C_{00}$ . The relative weights of  $V$  and  $k_{x,y}$  are set according to their ranges in the region of interest:

$$V_w \equiv 62.8 \text{ V} \cdot \text{m} \quad (15)$$

$$k_w \equiv 26.9 \text{ kV}.$$

The model is linear in the parameters, and the least-squares coefficients  $\mathbf{C}$  of this overdetermined system can be calculated by matrix inversion using singular-value decomposition (SVD) of the Vandermonde matrices of powers  $\mathbf{U}$  [10]:

$$\mathbf{U} \cdot \mathbf{C} = \mathbf{V}. \quad (16)$$

Explicitly, we have

$$\begin{pmatrix} v & v \cdot T_1\left(\frac{x_1}{a}\right) & v \cdot T_2\left(\frac{x_1}{a}\right) & v \cdot T_2\left(\frac{y_1}{a}\right) & v \cdot T_3\left(\frac{x_1}{a}\right) & v \cdot T_1\left(\frac{x_1}{a}\right) \cdot T_2\left(\frac{y_1}{a}\right) & \dots \\ \vdots & & & & & \vdots & \\ v & v \cdot T_1\left(\frac{x_M}{a}\right) & v \cdot T_2\left(\frac{x_M}{a}\right) & v \cdot T_2\left(\frac{y_M}{a}\right) & v \cdot T_3\left(\frac{x_M}{a}\right) & v \cdot T_1\left(\frac{x_M}{a}\right) \cdot T_2\left(\frac{y_M}{a}\right) & \dots \\ 0 & \kappa \cdot T_1'\left(\frac{x_1}{a}\right) & \kappa \cdot T_2'\left(\frac{x_1}{a}\right) & \kappa \cdot T_2\left(\frac{y_1}{a}\right) & \kappa \cdot T_3'\left(\frac{x_1}{a}\right) & \kappa \cdot T_1'\left(\frac{x_1}{a}\right) \cdot T_2\left(\frac{y_1}{a}\right) & \dots \\ \vdots & & & & & \vdots & \\ 0 & \kappa \cdot T_1'\left(\frac{x_M}{a}\right) & \kappa \cdot T_2'\left(\frac{x_M}{a}\right) & \kappa \cdot T_2\left(\frac{y_M}{a}\right) & \kappa \cdot T_3'\left(\frac{x_M}{a}\right) & \kappa \cdot T_1'\left(\frac{x_M}{a}\right) \cdot T_2\left(\frac{y_M}{a}\right) & \dots \\ 0 & \kappa \cdot T_1\left(\frac{x_1}{a}\right) & \kappa \cdot T_2\left(\frac{x_1}{a}\right) & \kappa \cdot T_2'\left(\frac{y_1}{a}\right) & \kappa \cdot T_3\left(\frac{x_1}{a}\right) & \kappa \cdot T_1\left(\frac{x_1}{a}\right) \cdot T_2'\left(\frac{y_1}{a}\right) & \dots \\ \vdots & & & & & \vdots & \\ 0 & \kappa \cdot T_1\left(\frac{x_M}{a}\right) & \kappa \cdot T_2\left(\frac{x_M}{a}\right) & \kappa \cdot T_2'\left(\frac{y_M}{a}\right) & \kappa \cdot T_3\left(\frac{x_M}{a}\right) & \kappa \cdot T_1\left(\frac{x_M}{a}\right) \cdot T_2'\left(\frac{y_M}{a}\right) & \dots \end{pmatrix} \cdot \begin{pmatrix} C_{00} \\ C_{10} \\ C_{20} \\ C_{02} \\ C_{30} \\ C_{12} \\ \vdots \end{pmatrix} = \begin{pmatrix} V_1/V_w \\ \vdots \\ V_M/V_w \\ (k_x)_1/k_w \\ \vdots \\ (k_x)_M/k_w \\ (k_y)_1/k_w \\ \vdots \\ (k_y)_M/k_w \end{pmatrix}, \quad (17)$$

where the factors  $v$  and  $\kappa$  are defined according to Eqs. 6, 9, and 15:

$$v \equiv \frac{1}{V_w} \quad (18)$$

$$\kappa \equiv -\frac{1}{a \cdot k_w}.$$

Once the coefficients  $\mathbf{C}$  are found, the fitted values  $\mathbf{F}$  and the residuals  $\mathbf{R}$  are calculated as follows:

$$\mathbf{F} = \mathbf{U} \cdot \mathbf{C} \quad (19)$$

$$\mathbf{R} = \mathbf{V} - \mathbf{F}. \quad (20)$$

An estimate of the random uncertainties on the coefficients is also provided by this procedure.

Figure 7 shows how the goodness of fit of the model (Eqs. 6, 8, and 9) varies as a function of the maximum order  $N$  of the power series. The reconstructed integrated potential and the distribution of residuals as

the order of the approximating polynomial increases are shown in Figure 8. At order  $N = 18$  (our chosen approximation), the standard deviation of the residuals of the integrated voltage is  $0.72 \text{ V} \cdot \text{m}$  (compared to a total range of  $62.8 \text{ V} \cdot \text{m}$ ). For the horizontal and vertical kicks, the standard deviations of residuals are  $50 \text{ V}$  and  $63 \text{ V}$ , respectively (over a total range of  $26.9 \text{ kV}$ ). Inspection of the voltage residuals (Figure 8), shows a systematic effect roughly proportional to the vertical derivative of the integrated potential, suggesting that the potential is not exactly symmetric with respect to  $y$ , but rather shifted by an amount of the order of the spacing of the fine mesh. This explains why the residuals do not decrease indefinitely with the order of the polynomial interpolation (Figure 7). This numerical artifact is negligible for our purposes.

The one-dimensional dependence of the calculated and fitted functions  $V(x, y)$ ,  $k_x(x, y)$ , and  $k_y(x, y)$  for a few sample cases is shown in Figure 9. The coefficients of the order  $N = 18$  polynomials and their statistical uncertainties are reported in Tables II and III. The interpolated cross derivatives (Eq. 12) are shown in Figure 10.

The polynomial expansions of the integrated fields (Eq. 9) and the corresponding momentum kicks (Eq. 2) are by definition symplectic and can be used in numerical tracking simulations to estimate their effect on beam dynamics.

## VI. DEPENDENCE OF THE RESULTS ON THE GEOMETRY OF THE SYSTEM

To study the sensitivity of the results to the geometry of the system, cases with different beam pipe radii and injection angles were simulated. The chosen beam pipe radii were  $35 \text{ mm}$ ,  $40 \text{ mm}$  (reference case), and  $45 \text{ mm}$ . These are the inner radii of both the main pipe and the injection pipe. The chosen bend angles were  $25 \text{ deg}$ ,  $30 \text{ deg}$  (reference case), and  $35 \text{ deg}$ . These are the angles spanned by the electron beam. Figure 11 shows the electrostatic potential on the bend plane ( $y = 0$ ) for each of these 5 cases.

The calculated kick maps are compared in Figure 12. They look qualitatively very similar. A quantitative comparison is presented in Figure 13. Because the grid points are not exactly the same in each case, we randomly select 4096 points in the region of interest ( $|x| \leq 10\sigma_p$  and  $|y| \leq 10\sigma_p$ ) and calculate the average kicks in their neighborhood for each case. The neighborhood is defined as 2 times the spacing of the fine grid. The histograms of the differences between the average kicks, divided by the arbitrary kick scale  $k_{\text{scale}} = 10 \text{ kV}$ , are shown in Figure 13. The changes in geometry considered in this study amount to a change in the kicks limited to about 2.3% (or  $0.23 \text{ kV}$ ).

## VII. CONCLUSIONS

The electrostatic fields generated by the bends in an electron lens were calculated. The corresponding symplectic kick maps were provided as coefficients of truncated power series of orthogonal polynomials for evaluation with analytical formulas. The goal is to assess some of the effects of electron-lens asymmetries on the circulating beam in the case of the proposed proton halo scraper for the LHC. The same technique can be applied to electron lenses with different current-density profiles (Gaussian, flat, etc.) to study perturbations in nonlinear integrable optics for the IOTA ring at Fermilab.

The present work may be further extended by taking into account the space-charge evolution of the electron beam, the magnetic fields, and longitudinal proton dynamics.

## FIGURES

FIG. 1. Layout of a Tevatron electron lens. The beam is generated in the electron gun inside a conventional solenoid and guided by strong axial magnetic fields. Inside the superconducting main solenoid, the circulating beam interacts with the electromagnetic fields generated by the electrons' charge distribution. The electron beam is then extracted and deposited in the collector. Dimensions are in millimeters.

FIG. 2. The distribution of electron macroparticles mimicks a section of the hollow electron beam. (At this magnification, the hole around the curved electron beam axis is not visible.)

FIG. 3. Conductor geometry and calculated electrostatic potential on the plane of the bent electron distribution. The contour lines are marked with the potential in kilovolts.

FIG. 4. Calculated electrostatic fields on the axis of the proton beam ( $x = 0$ ,  $y = 0$ ).

FIG. 5. Contour plot of the integrated potential  $V(x,y)$ . The contour lines are labeled in units of  $\text{V} \cdot \text{m}$ .

FIG. 6. Contour plot of the integrated fields  $k_x(x,y)$  and  $k_y(x,y)$ . The contour lines are labeled in units of kV.

FIG. 7. Goodness of fit vs. order of the Chebyshev polynomial model. The maximum residuals and the standard deviations of the residuals are plotted as a function of the maximum order of the power series: integrated potential  $V$  (left); kicks  $k_x$  and  $k_y$  (right).

FIG. 8. Successive polynomial reconstructions of the integrated potential  $V(x, y)$  (first column) and kicks  $k_x(x, y)$ ,  $k_y(x, y)$  (third and fifth columns) and the corresponding residuals (even columns). Contour line labels are in units of  $V \cdot m$  for the integrated potential and of kV for the kicks. For clarity, only the pattern of the residuals is shown; their magnitude can be inferred from Figure 7. The number  $N$  is the maximum order of the polynomial. The first 5 rows show the polynomial approximations. The bottom row shows the target maps (i.e., the Warp calculation).

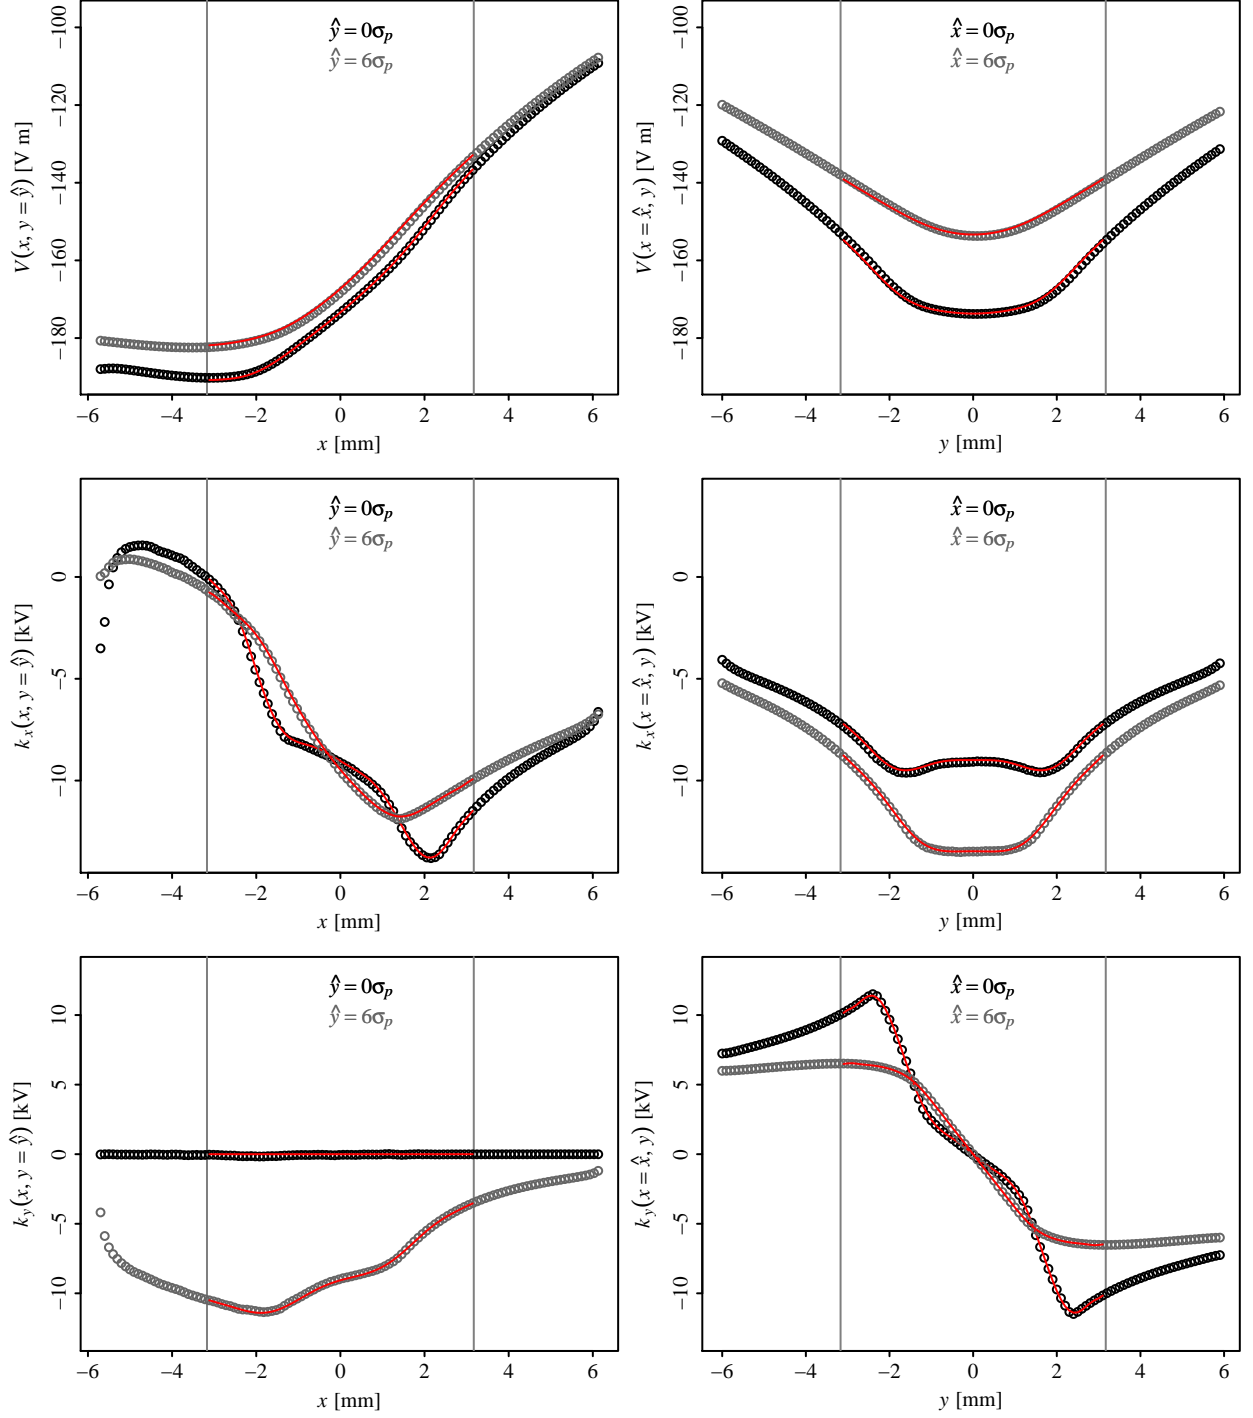

FIG. 9. One-dimensional dependence of the integrated potential  $V$  and of the kicks  $k_x$  and  $k_y$  on the transverse coordinates  $x$  and  $y$ , for 2 sample values of the other coordinate. The empty circles represent the Warp field calculation on the fine mesh, whereas the lines represent the polynomial interpolation up to order  $N = 18$ . The vertical gray lines represent the region of interest,  $|x| \leq 10\sigma_p$  and  $|y| \leq 10\sigma_p$ .

FIG. 10. Contour plot of the interpolated cross derivatives  $\partial k_x / \partial y = \partial k_y / \partial x$  up to order  $N = 18$  from Eq. 12. The contour lines are in units of kV/mm.

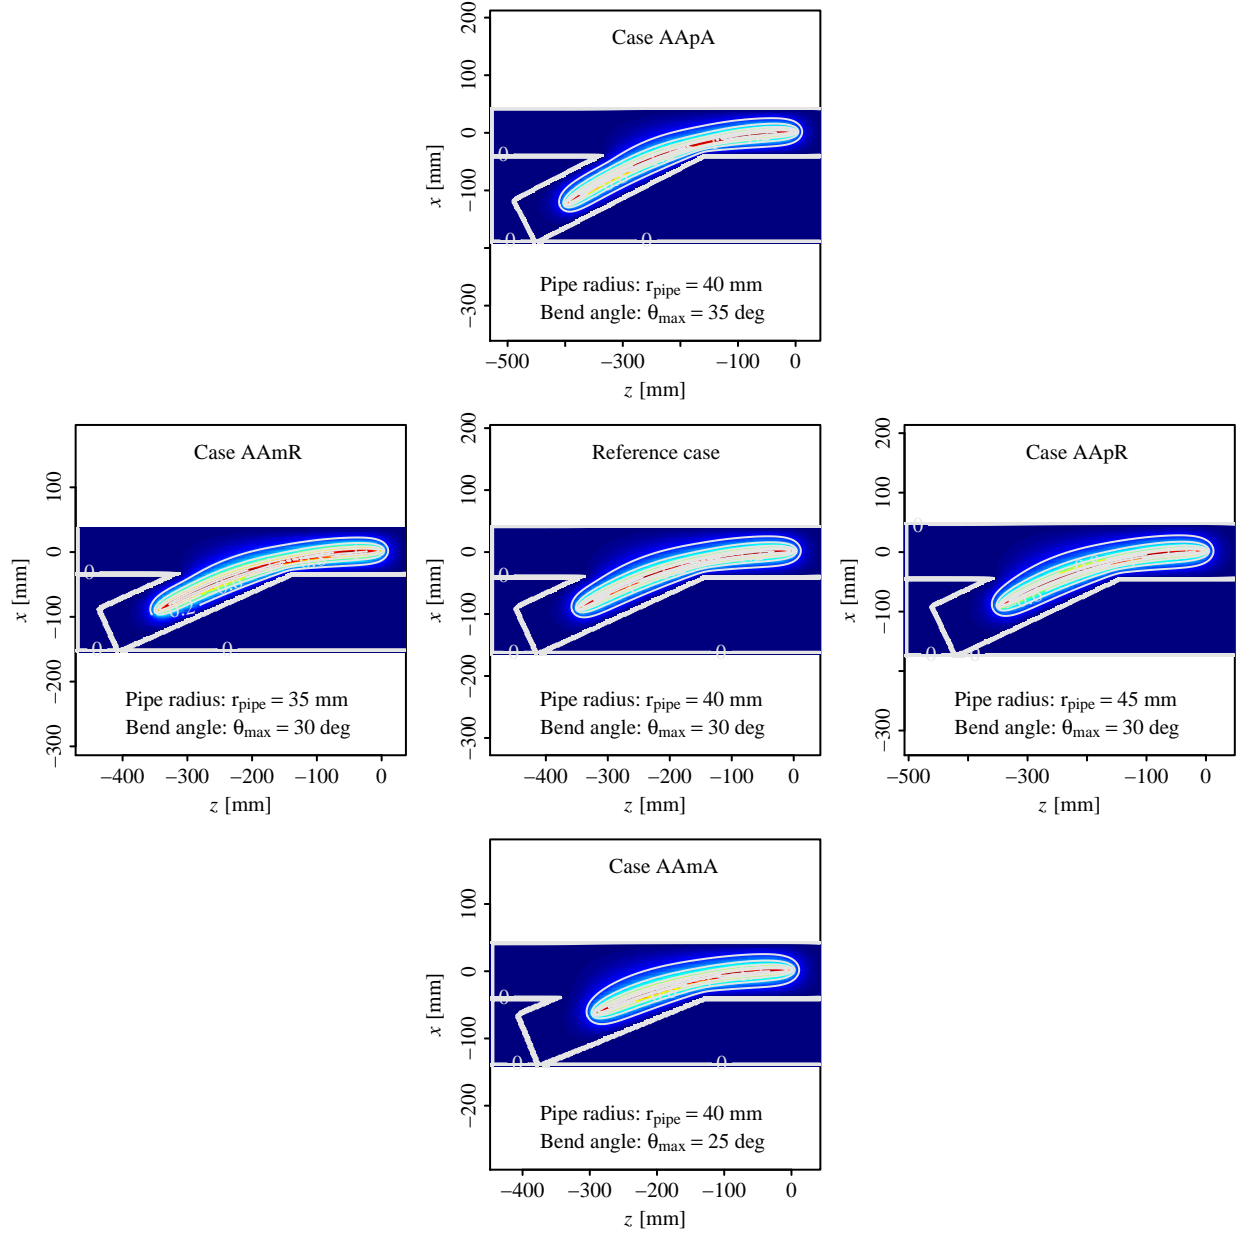

FIG. 11. Conductor geometry and potential on the bend plane for each simulated case.

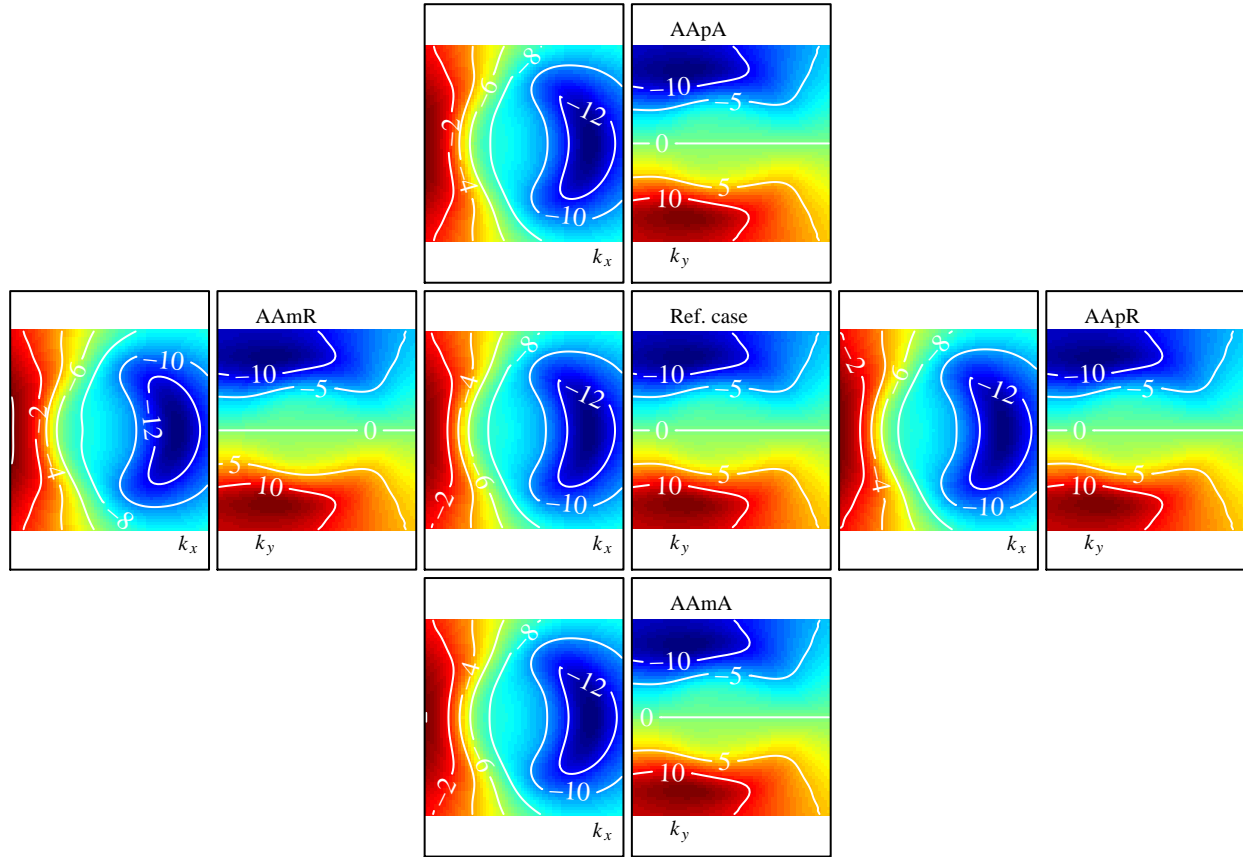

FIG. 12. Comparison of the kick maps for the 5 simulated cases, in the same order as Figure 11.

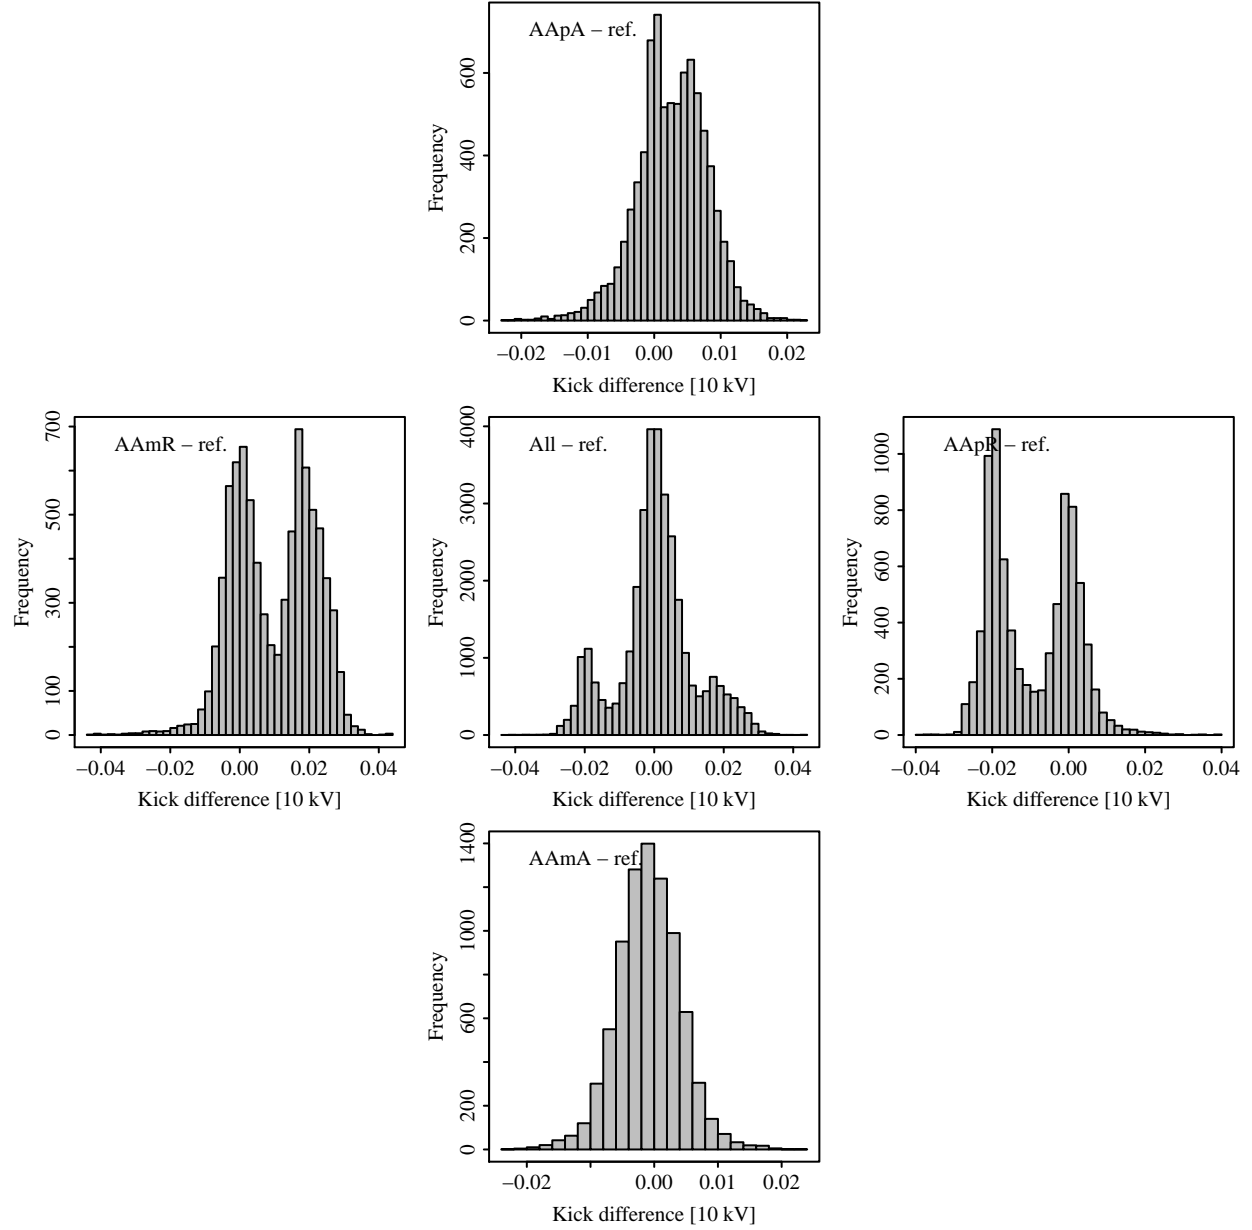

FIG. 13. Comparison of the kicks at 4096 random points within the region of interest for the 5 simulated cases with different geometries. The histograms show the scaled differences between the kicks at the corresponding locations. The central histogram contains all the differences between the modified cases and the reference case.
